Learning with Computer Games:
Micro Level Feedback and Interventions

Key words: *Game-based Learning, Feedback, Didactic Interventions, Non-invasive Knowledge Assessment, Micro Adaptivity*

Abstract:

The idea of utilizing computer games for educational purposes is not new and grounds on the simple fact that playing is one of the most natural forms of learning. Advantages of digital games are that they offer a meaningful context, rich visualizations, and interactivity. Successful educational games, however, require a subtle balance between learning and gaming as well as challenge and ability. Thus, an AI is required that can assess knowledge, learning progress, and motivational-emotional states without compromising the flow of the game. Moreover, non-invasive interventions and feedback is necessary to support and guide the learner. The present paper describes the effects, based on empirical research, of such individualized guidance and feedback on problem solving and learning behaviour.

1   Introduction

The majority of current approaches to technology-enhanced learning are based on traditional, unexciting 2D user interfaces. At the same time, this view is compounded by the proliferation of immersive recreational computer games. In addition, traditional interfaces for educational applications have distinct weaknesses from the perspectives of learning psychology and didactics. For example, they are not intrinsically motivational and it is difficult to retain a learner's interest, to provide a meaningful context throughout learning episodes, or to activate prior knowledge as a basis for learning. Moreover, it is not always possible to provide real-world problems for practicing new knowledge and a purposeful application of new knowledge is difficult without a meaningful and engaging context.

Immersive digital educational games (DEG) offer a highly promising approach to make learning more engaging, satisfying, inspiring, and probably more effective. Thus, it is not surprising that currently there is significant hype over game-based learning. Many of the characteristics of DEGs (e.g., interactivity, feedback, problem solving) are considered to be important for successful and effective learning. The very nature of utilizing (computer) games for learning is that playing games is one of the most natural forms of learning. Children start learning to talk by playing with noises or they learn collaboration and strategic thinking when playing *Cowboys and Indians*. Since the 1990s research and development has increasingly addressed learning aspects of playing recreational games and also the realization of computer games for primarily educational purposes.

Still, DEGs have major disadvantages such as difficulties in providing an appropriate balance between gaming and learning activities or between challenge and ability, in aligning

the game with national curricula, or the extensive costs of developing high quality games. Thus, DEGs most often cannot compete with commercial counterparts in terms of gaming experience, immersive and interactive environments, narrative, or motivation to play. Moreover, most educational games do not rely on sound instructional models, leading to a separation of learning from gaming; often they provide gaming actions only as reward for learning. Existing DEGs do not differ significantly from other multimedia learning objects and applications and there is considerable debate regarding the power of games for educational purposes, the advantages, disadvantages, costs, and risks.

In conclusion, the attempt to utilize - at least parts of - gaming activities for educational purposes and to utilize the educational potential of computer games is a highly promising approach to facilitate learning and to make it a more pleasant task. A crucial factor, undoubtedly, is an appropriate balance; a balance between learning and gaming and a balance between challenge and ability (in terms of gaming as well as learning); particularly when targeting at older children and adolescents. It is important to maintain fun, immersion, flow experience, and motivation – the motivation to play and therefore to learn. Moreover, it is important to realize a gaming experience that can compete with that of commercial, non-educational games.

Successful DEGs must be able to adapt to the learner's knowledge, skills, and abilities, motivation, and also to pedagogical implications. In traditional forms of technology-enhanced learning, concepts of adaptivity, adaptability, and personalization are increasingly important. Generally, adaptive approaches to e-learning contest the one-fits-all approach of traditional learning environments, trying to tailor the learning environment according to individual needs and preferences. *Adaptivity* refers to navigation, curriculum sequencing, and presentation. For example, an adaptive system may only provide learning objects which are suitable for an individual's learning progress - learning objects either too difficult or too easy might not be displayed in order to avoid visual and cognitive load and to suggest an appropriate learning path through the learning content.

In the context of immersive digital games, existing approaches to adaptivity must be extended in order to maintain an immersive gaming experience, motivation, and probably flow experience by suitable adaptive. A special challenge in this context arises from the need for pedagogical support during learning - and therefore embedded in gaming. At many staves of the learning ladder, from a psych-pedagogical perspective, support and feedback is necessary in order to ensure successful, effective, and complacent learning. Considering the importance of not destroying immersion, flow, and engagement in the game, the assessment of the learning progress and psycho-pedagogical feedback must occur in a non-invasive way. This, however, requires an intelligent system that is capable of assessing individual competences and learning progress by observing and interpreting the learner's behaviour in the learning situations within the game.

The research presented here primarily grounds on the ELEKTRA project (www.elektra-project.org), which was a multi-disciplinary research and development project, running from 2006 to 2008, funded by the European Commission. It had the ambitious goal to utilize the advantages of computer games and their design fundamentals for educational purposes and to address disadvantages of game-based learning as far as possible. Within the project a methodology for successful design of educational games has been established and a game demonstrator was developed based on a state-of-the-art 3D adventure game teaching optics according to national (i.e., French, Belgian, and German) curricula [1]. More importantly, ELEKTRA addressed research questions concerning data model design as basis for adaptivity and resource description enabling interoperability of systems as well as the data model itself [2]. In the course of the project, an approach to adaptivity, that is, *micro adaptivity*, was developed that allows assessing learning performance and cognitive states in a non-invasive way by interpreting the learners' behaviour within the game and by responding on the

conclusions drawn from their behaviour [3]. Attuned to the assessed competencies (or lack of competencies), meaningful feedback, for example hints, suggestions, reminders, critical questions, or praise, can be triggered, without destroying the gaming experience.

2   Non-Invasive Knowledge Assessment

The very basis for a suitable educational support is to assess the learner's knowledge and learning progress. As mentioned, this must occur in a non-invasive, "stealth" way in order not to compromise the gaming experience and flow. To achieve such type of assessment, a theoretical and technological approach is required that enables the game to assess cognitive states (e.g., competence states or motivational states), learning progress, possible misconceptions, or undirected/unsuccessful problem solving strategies
Our approach is based on a combination of *Competence-based Knowledge Space Theory* (CbKST), which has been successfully utilized in conventional adaptive, personalized e-learning, and theories of problem solving. CbKST provides a detailed domain model that includes a set of meaningful competence states as well as a set of possible learning paths.

Very briefly, CbKST is an extension of the originally behavioral Knowledge Space Theory by Doignon and Falmagne [4] where a knowledge domain is characterized by a set of problems. The knowledge state of an individual is identified on the subset of problems this person is capable of solving. Due to mutual dependencies between the problems captured by *prerequisite relations*, not all potential *knowledge states* will occur. The collection of all possible states is called a *knowledge structure*. To account for the fact that a problem might have several prerequisites (i.e., and/or-type relations) the notion of a *prerequisite function* was introduced. The basic idea of CbKST is to assume a set S of abstract skills underlying a domain of knowledge. The relationships between the skills and problems are established by a *skill function*. Such function assigns a collection of subsets of skills (i.e., *competence states*) to each problem, which are relevant for solving it. By associating skills to the problems of a domain, a knowledge structure on the set of problems is induced. The skills, which are not directly observable, can be uncovered on the basis of a person's observable performance. A further extension is to assume prerequisite relations between the skills, inducing a competence structure on the set of skills [5].

To achieve a non-invasive assessment, we developed a formal model of the problem solving behaviour in game-based learning situations (LeS). Basically, LeS are characterized by a large degree of freedom and complex problem solving demands. The problem solution process is considered to be a meaningful sequence of problem solution states establishing a problem space [6]. Stochastic process models are applied in order to estimate the probabilities of certain state transitions and to estimate the probability of reaching a solution state (within a specific time interval). In other terms, a LeS is segmented in to a set of possible problem solution states (you may think about all possible states of the Tower of Hanoi problem). Each of those problem solution states is mapped, through an ontology, to one of a set of possible competence states. By this means, the game can interpret the behaviour of the learner in terms of available knowledge, un-activated knowledge, or missing knowledge, by mapping the actions of the learner to competence states [3].

The overall micro adaptive assessment and intervention process is imitated by any action (event) the learner is performing in the game (e.g., by switching on a torch). The situation after such event is analyzed in terms of the given problem solution state and, subsequently, the probability distribution over all competence states is adjusted to the problem solution state. By the probability change of specific competencies involved in a situation (e.g., knowing that the torch's light is necessary), the most relevant/critical competencies can be detected. Depending on an increase (what actually is desired) or a decrease of the probability of specific competencies, pedagogical/didactic meta-rules are utilized to select a specific

interventions and feedback (e.g., 'if the probability of a competence v involved in a LeS decreases below a threshold w, and the probability of a competence x is above a value y, then trigger an educational hint z').

From a technical perspective, the architecture consists of four modules or engines (Figure 1). The learner is connected to the system through the game engine. It provides the non-adaptive parts of the game, and as such it is also the user interface to the system. The game engine provides information on the learner's action in the game to the skill assessment engine. This engine updates the learner model (i.e., the competence state probabilities) according to aforementioned process and additional information from an ontology. The resulting information about the learner's competence state and its changes are then forwarded to the Educational Reasoner, the pedagogical part of micro adaptivity. Based on pedagogical rules (e.g., the diversification principle) and learning objectives (e.g., the straight propagation of light), the reasoner gives recommendations on adaptive interventions to the adaptation realization module which maps the abstractly formulated educational recommendations onto more concrete game recommendations. In this mapping process, data on game elements and information on previously given recommendations are considered. The game recommendations are then forwarded to the game engine, which realizes them as concrete adaptive interventions in the game.

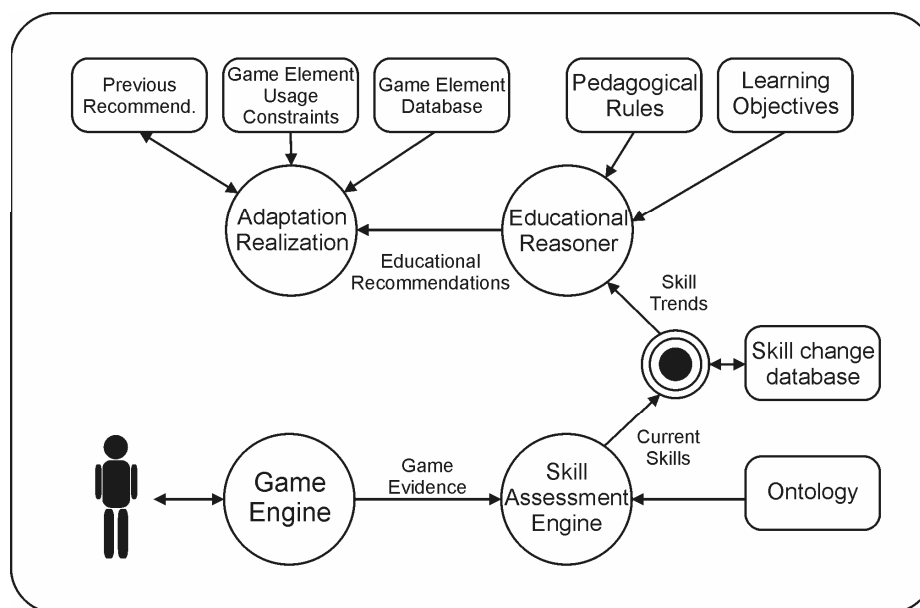

Figure 1: An architecture for micro adaptive assessment and interventions.

3   Feedback and Educational Interventions

Pedagogical interventions and feedback are important aspects in educational settings. They guide the learning process, inform the learner about the learning progress and possible deviations from a planned learning path, and they aim to provide the learner with appropriate information and direct the learner's view on important information. Generally, feedback on learning comes from teachers, fellow students, friends, or from oneself (then it is called reflection). The empirical research on the effects of such type of educational interventions revealed ambiguous results. A meta-analysis of Azevedo and colleagues [7] yielded that in some cases interventions and feedback support the learning success, in some context, however, learning may be impaired by the disruptive potential of interventions.

Two questions arise with respect to interventions and feedback. First, do interventions/feedback, although designed to be non-invasive, on educational issues impair gaming experience? Second, can interventions in gaming situations facilitate the learning progress or do they increase the learner's cognitive load, which was suggested be several researchers. In the context of the ELEKTRA project, we implemented the theoretical framework of micro adaptivity in the game demonstrator. This demonstrator is a state-of-the art 3D adventure game teaching physics in relation to national school curricula for the age group of 12 to 14 years. For evaluation purposes, log files of the gaming sessions were recorded and, in addition, questionnaires and performance tests were presented.

4   Empirical Findings

In the context of the ELEKTRA project, we investigated the effects of different types of interventions and feedback with French students playing the demonstrator game. Essentially, the demonstrator is based on a classical 3D adventure game in first-person view. The aim is to salvage the girl Lisa and her uncle Leo who have been kidnapped by the evil Black Galileans; moreover, the learner has to avert that those evil forces possess to entire world. During this journey, the learner needs to acquire specific, curriculum-related knowledge and skills, concretely, the learner learns about 8th grade optics. The learning occurs in different ways, ranging from hearing or reading to freely experimenting. After finding a magic hour glass, the learner is in company of the ghost of Galileo Galilei, who is the learner's (hidden) teacher. In addition, the learner can interact with Lisa via a headset, which is indicated in the upper left corner of the screen. Those non-playing characters also play a significant role for intelligent, non-invasive educational and motivational interventions. For example, Galileo tells the learner specific facts, which are need for certain events in the game, or he intervenes by providing the learner with certain hints or feedback. Figure 4 gives some impressions about the demonstrator game.

In contrast to previous research on the (educational) effects of interventions and feedback, as briefly outlined above, the focus in the present work was on the effects of adaptive, personalized, highly appropriate, and timely interventions in comparison to no interventions, neutral interventions, or even inappropriate and ill-suited interventions.

4.1   Experimental Design

The scientifically sound comparison of feedback effects in a highly adaptive and individualize context, as aspired with micro adaptivity, is highly complex. The main idea of adaptation and personalization is that each of the learners/players/participants receives entirely different interventions, tailored to individual knowledge as well as learning and gaming progress. The consequence for the experimental design is that an exact comparison of different participants is not possible.

To address that problem, we utilized a so-called yoked control design [8] the demonstrator. Yoked control is based on the idea that comparable pairs of participants are actively generated. A first participant receives a treatment (e.g., an intervention) that is adaptively tailored to his/her behaviour. A second participant is artificially linked to the first by receiving exactly the same treatment as the first one, of course, now the treatment is entirely independent from the participant's behaviour. From the experimental perspective, both participants did now receive identical and, therefore, comparable gaming/learning experiences. The necessary event logging and replay functions have been implemented in the demonstrator game.

Figure 2: These are four screenshots from the ELEKTRA demonstrator game. The game starts outside a villa near a science park (upper left image). In the villa the learner faces, among others, the task to open a solid metal door, which requires some knowledge about the propagation of light (upper right image). The ghost of Galileo Galilei is the learner's accompanying mentor and teacher (lower left image). To acquire knowledge and to precede through the game the learner is doing specific experiments, supported by Galileo and, via a headset indicated in the upper left corner of the screen, Lisa (lower right image).

   Yoked control assures that a matched pair of participants received exactly the same interventions and feedback independent from their actions and their progress in the game. However, yoked control cannot avoid that the second participant receives an intervention or feedback that is by chance suitable for the situation. For example, the feedback 'well done' is suitable in many situations. To address this problem, statistical analyses were based on four types of interventions/feedback based on the data gathered by yoked design experiments:

- Appropriate interventions/feedback (i.e., statements that are beneficial for the learning or gaming progress, for example, "remember what I told you about the propagation of light" when trying to open a door by hitting a light sensor with a narrow beam of light; Figure 2).
- Neutral interventions/feedback (i.e., statements that are always suitable and that do not have much positive or negative effects, for example, "keep a stiff upper lip")

- Inappropriate interventions/feedback (i.e., statements that have a negative or at least confusion impact on learning or gaming, for example, "remember what I told you about the propagation of light" when actually solving the Tower of Hanoi problem).
- No interventions/feedback

To identify the categories, we performed extensive log file analyses for the yoked control group, comparing the received interventions/feedback with the actual behaviour. The manual classification work was performed by two raters independently.

The basis of the present analyses is the so-called "slope device" situation. In this LeS the students experiment with a machine where several balls of different materials (solid and hollow iron, wood, and plastic) are running down a slope and also a laser can beam down this slope. This machine has a fan and a strong magnet. The learners' task is to make the balls fall into a hole by setting appropriate values for fan and magnet. In addition they should estimate the trajectory of the laser beam in dependence fan, gravity, and magnetic force. This experiment should visualize the effects of fan, gravity, and magnet on different material and, first of all, that the laser beam is not influenced by such external forces and independently propagates in a straight line. The approach to solution value indicates how fast a learner finds the correct settings of fan and magnet and how well s/he can estimate the trajectory of the laser beam.

Participants were 40 school students recruited at two schools in Paris; 17 were female, 23 male. The average age was 13.08 years (SD = 1.08). By far the largest group (i.e., 90%) of the children were familiar with computer games, playing about 6.01 hours (SD =8.88) a week.

4.2   Results

In a first step, we analysed how fast and how well the learners could accomplish the slope device experiments, depending on the type of interventions/feedback they received. This is probably the most meaningful perspective to the gaming behaviour since this kind of support is the major purpose of the interventions. In this context we distinguished two measures. First, the so-called 'approach to solution' variable, which states how many action were performed following a certain type of intervention/feedback that were (a) closer to the final solution, (b) farther from that, or (c) without an effect. The value of this variable depends on the number of interventions of a type each learner received. Second, we analyzed the response time that is, the time the learners needed after receiving an intervention/feedback to perform their next actions in the experiments. Since this type of analysis compares intervention/feedback types and not participants (each of them got several of different types), the total experimenting time is not a meaningful measure.

The results of these analyses are summarized in Figure 3. Appropriate interventions/feedback resulted in an average approach to the correct solution of 4.95 (SD = 18.37), neutral in an average approach of 3.69 (SD = 16.31), inappropriate in an average approach of 4.00 (SD = 15.21), and not receiving any interventions or feedback resulted in an average approach of 3.76 (SD = 14.30). These differences are statistically not significant. However, they clearly indicate that appropriate interventions/feedback result in a quicker problem solving progress that needs fewer steps. Somewhat different results were found for the response times after each intervention/feedback. Appropriate interventions/feedback resulted in an average response time of 3.90s (SD = 1.16), neutral in an average response time of 4.03s (SD = 1.08), inappropriate in an average response time of 3.94s (SD = 0.84), and not receiving any interventions or feedback resulted in an average response time of 3.06s (SD = 0.90). An analysis of variance (ANOVA) yielded that receiving no interventions or feedback resulted in statistically significant shorter response times (F(3)=33,86; p<01) than receiving interventions or feedback; the type of feedback, however, did no influence response times.
Figure 3: The left panel illustrates the average approach to the correct solution of the slop device experiments. The right panel illustrates the response time after receiving an intervention/feedback.

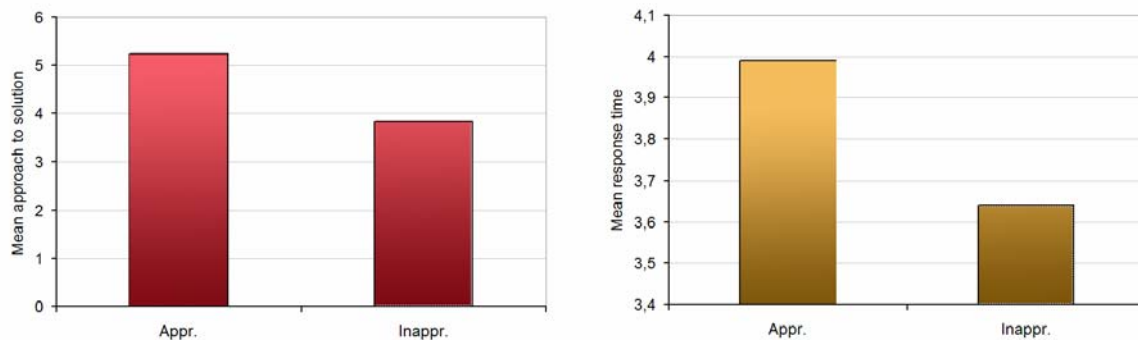

Figure 4: The left panel illustrates the average approach to the correct solution of the slop device experiments for extreme groups with a high and a low amount of inappropriate interventions/feedback. The right panel illustrates the corresponding response time.

In addition to the analysis on the intervention type level, we performed analyses on the learner level. We compared the average approach to the correct solution and the average response time for participants who received (almost) no inappropriate interventions and feedback with such participants who received a large portion of inappropriate interventions. The reason for analyzing extreme groups is that, due to the highly adaptive nature of the game and also due to the yoked control design, the distribution of specific types of interventions is flowing and does not allow clearly identifying specific groups on the person level. The extreme groups included 10% of participants who had received the most inappropriate interventions and the least inappropriate interventions respectively. The results are summarized in Figure 4. The average approach to the correct solution was 5.23 (SD = 14.17) in the appropriate intervention extreme group and 3.83 (SD = 16.20) in the inappropriate intervention extreme group. Similarly, the average response times were 3.99s (SD = 0.91) in the appropriate intervention extreme group and 3.64s (SD = 1.02) in the inappropriate intervention extreme group. According to an ANOVA, the differences between the extreme groups were statistically significant for both approach to solution (F(1)=0,31, p<0,01) and response time (F(1)=5,05; p<0,05).

So far, analyses focussed on the participants' behaviour within the game and on how quickly and how well they could handle the problems of the slope device experiments. In addition to that, a major question is if the participants learned what they were supposed to learn with the slope device LeS and how well they performed. Thus, in a next step we

Table 2: Average learning performance.

		Adaptive Interventions	No Interventions
Pre test	Learning outcome	9,60 (3,49)	8,28 (3,07)
	I don't know answers	3,40 (2,22)	4,46 (3,02)
	Incorrect answers	8,00 (3,23)	8,26 (2,72))
Post test	Learning outcome	10,60 (4,04)	9,11 (3,95)
	I don't know answers	3,15 (2,37)	3,68 (3,55)
	Incorrect answers	7,25 (3,56)	8,20 (3,77)
	Learning performance	1,00 (2,45)	0,83 (3,91)

analysed learning performance depending on aforementioned extreme groups. From a general multiple choice learning test, covering the learning objectives of the entire demonstrator game, eight items were related to the slope device experiments. Table 1 lists the descriptive values. Summarized over all items, the appropriate interventions extreme group performed clearly better (45% correctly solved items) than the inappropriate interventions extreme group (35% correctly solved items). This performance was also correlated with gaming duration; the

longer the participants played with the demonstrator game, the better was their test performance (r = .351; p = .029).

Finally, we analyzed overall learning outcomes with the demonstrator game with and without interventions/feedback using the 34 item knowledge test before and after playing the demonstrator. The results are summarized in Table 2. The group with adaptive interventions clearly performed better in the knowledge test than the group without any interventions.

5   Conclusions

The work presented here has its origin in the ELKTRA project and its demonstrator game. This game technically implements a theoretical approach to non-invasive personalization by interventions and feedback within a complex and fragile game context including all its constraints. To collect empirical evidence on the effects and efficacy of micro adaptive assessment and interventions, we conducted several evaluation sessions with the demonstrator game, focusing on different aspects of game-based learning, assessment, and particularly interventions and feedback.

In general, the literature indicates pros and cons of (immediate) feedback in learning contexts. On the one hand, interventions may have a disruptive influence on concentration and immersion and may decrease the learner's efforts by providing solutions. On the other hand, appropriate interventions an guide the learner in a meaningful way and support learning by providing appropriate information.

The present evaluation the ELEKTRA demonstrator game, and particularly the slope device LeS, provide some evidence that the degree of appropriateness of an intervention is key to its impact and success. We could show that micro adaptive interventions lead to a faster approach to the correct solution, meaning to a faster problem solving process, in problem solving situation than neutral, inappropriate, or no interventions. In addition, we could demonstrate that providing the learner with appropriate, personalized interventions resulted in a better learning performance with the demonstrator game in comparison to providing no interventions at all.

The progress in the state-of-the-art in DEGs and game-based learning made with the ELEKTRA project is taken up by the 80Days project. 80Days (www.eightydays.eu) is a multi-disciplinary research and development project, running from 2008 to 2010, funded by the European Commission. This projects aims to advance the approaches to micro adaptive assessment and interventions and it aims to introduce an approach to macro adaptivity by interactive and personalized storytelling.
